This criticism is still valid, although it is in a sense. After all, the hypothesis claiming that infants are perceiving a 2D image is better supported by empirical data than the alternative hypothesis claiming that infants are perceiving a 3D. The above, however, tend to be extremely hard to justify through experiments. For example, any "photographic mind" example that seems to show a preference for photographs over paintings has to be tested in ways that leave open the possibility of other factors being responsible, or it's not actually a photographic mind example.. much evidence is very much in line with this proposal, despite the fact that the picture preference for photographs seems to be limited to Western societies. Developments in the understanding of the basis for photographic detection have led to a series of experimental demonstrations to try to explain how this ability may be possible. The basis for the widespread visual recognition of images is unclear, however, it is likely that there are multiple mechanisms each responsible for a different set of image stimuli. The basis for the preference for photographs over paintings may be simpler, however, because the binding of image is necessary for other perceptual abilities. It seems likely that the ability to detect a photograph as a photograph is not based on any set of generalised theories but on the basis of an "experience" of what a photograph should be. Detection as a whole is based on trial and error processes (Rensink and O'Regan, 1999), but the mechanisms that underlie detection are specific
